MVPS Detection-Latency Reconciliation: A Unified
Onset-Phase Lemma for Multi-Vantage Coherence
Profiles
draft-melegassi-ippm-mvps-latency-reconciliation-00

Abstract

Several Multi-Vantage Path Snapshot (MVPS) profiles state a detection-latency bound as a function of the detection multiplier M and the control-tick period T_{tick} . The bandwidth-efficient profile [I-D.melegassi-mvps-incremental-be] states it as $M \cdot T_{\text{tick}}$; the Coherence-BFD [I-D.melegassi-coherence-bfd] and DDoS-Resilience [I-D.melegassi-mvps-ddos-resilience] profiles state it as $(M-1) \cdot T_{\text{tick}}$. A reviewer reading two profiles in parallel observes a one-tick disagreement.

This document shows the disagreement is not a mathematical error but an unstated difference in the ONSET-PHASE convention, and closes it with a single Unified Detection-Latency Lemma (L_{DL}):

$$\text{tau_detect}(\phi) = M \cdot T_{\text{tick}} - \phi + \text{tau_RTT}, \quad \phi \text{ in } [0, T_{\text{tick}})$$

whose best case is $(M-1) \cdot T_{\text{tick}} + \text{tau_RTT}$, worst case is $M \cdot T_{\text{tick}} + \text{tau_RTT}$, and expected (uniform-phase) case is $(M-1/2) \cdot T_{\text{tick}} + \text{tau_RTT}$. All three published statements are then correct simultaneously, as different points of one one-parameter family. The lemma is numerically validated to the millisecond against the published benchmark receipt by `scripts/validate_detection_latency_lemma.py` (PASS, max error 0 ms) and recorded in `evidence/detection_latency_lemma_receipt.json`.

This document introduces no new wire format, requests no IANA action, and changes no MVPS v4.0 theorem; it is a clarifying lemma plus a recommended reporting convention.

Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of BCP 78 and BCP 79.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at <https://datatracker.ietf.org/drafts/current/>.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on 29 November 2026.

1. Introduction

1.1. The One-Tick Disagreement

The MVPS profiles share a common detection pipeline: a broker advances a global tick counter at a fixed period T_{tick} , each tick window yields one coherence observation, and an alarm fires after the M -th consecutive above-threshold observation. The latency from the anomaly onset to the moment a subscriber may act is the detection latency τ_{detect} .

Three profiles state τ_{detect} differently:

- o [I-D.melegassi-mvps-incremental-be], Theorem 9:
 $\tau_{\text{detect}} \geq \max(M \cdot T_{\text{tick}}, \tau_{\text{RTT}}, \tau_{\text{C4}})$.
- o [I-D.melegassi-coherence-bfd], Section 12.1:
detection latency 100 ms = $(M-1) \cdot T_{\text{tick}} = 2 \cdot 50$ ms.
- o [I-D.melegassi-mvps-ddos-resilience], Theorem D1:
 $\tau_{\text{detect}} = (M-1) \cdot T_{\text{tick}}$ for all $R \geq R_{\text{sat}}$.

The first uses $M \cdot T_{\text{tick}}$; the latter two use $(M-1) \cdot T_{\text{tick}}$. A reviewer reading them in parallel sees a disagreement of exactly one tick. Each profile is internally consistent, but each assumes a different, unstated convention for WHERE in a tick window the anomaly onset falls. This document makes that convention explicit and binds all three statements to one lemma.

1.2. Scope and Non-Goals

This document:

- o defines the onset-phase model (Section 3),
- o proves the Unified Detection-Latency Lemma L_{DL} (Section 4),
- o maps each profile's statement to a point of the L_{DL} family (Section 5),
- o reproduces the benchmark receipt (Section 6), and
- o recommends a single reporting convention (Section 7).

This document does NOT introduce a wire format, does NOT request any IANA action, and does NOT alter any MVPS v4.0 theorem. It is a clarifying lemma and a reporting recommendation.

2. Terminology and Conventions

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "NOT RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in BCP 14 [RFC2119] [RFC8174] when, and only when, they appear in all capitals, as shown here.

T_{tick} :

The fixed control-tick period of the broker ($T_{tick} > 0$).

M :

Detection multiplier: the number of consecutive above-threshold observations REQUIRED before an alarm fires ($M \geq 1$).

τ_{RTT} :

One-way signalling latency from broker alarm to subscriber action ($\tau_{RTT} \geq 0$).

Onset (t_0):

The instant at which the coherence surface departs from baseline by an amount that exceeds the alarm threshold in any subsequent tick window. Onset need not coincide with a tick boundary.

Onset phase (ϕ):

$\phi = t_0 - \text{floor}(t_0 / T_{tick}) * T_{tick}$, in $[0, T_{tick})$.

3. Onset-Phase Model

The broker advances the tick counter at $t_k = k * T_{tick}$ for k in $\{0, 1, 2, \dots\}$.

Let $k_0 = \text{floor}(t_0 / T_{tick})$ be the index of the tick window containing the onset, and $\phi = t_0 - k_0 * T_{tick}$ the onset phase.

Under the standard CLOSED-LEFT, OPEN-RIGHT window convention, a tick window $[t_k, t_{k+1})$ emits its observation at t_{k+1} ; the FIRST CAPTURED TICK (the first window whose observation reflects the onset) therefore has index $k_0 + 1$.

An alarm fires after the M -th consecutive above-threshold observation, i.e. at tick index $k_0 + M$, at the instant $t_{\text{alarm}} = (k_0 + M) * T_{tick}$. The subscriber may act at $t_{\text{act}} = t_{\text{alarm}} + \tau_{RTT}$, and $\tau_{\text{detect}} = t_{\text{act}} - t_0$.

4. The Unified Detection-Latency Lemma (L_DL)

LEMMA L_DL (Unified Detection-Latency). Under the model of Section 3, for any fixed $M \geq 1$, $T_{\text{tick}} > 0$, and $\tau_{\text{RTT}} \geq 0$, the detection latency is a function of the onset phase ϕ in $[0, T_{\text{tick}})$:

$$\tau_{\text{detect}}(\phi) = M \cdot T_{\text{tick}} - \phi + \tau_{\text{RTT}}. \quad (1)$$

Consequently:

(a) BEST CASE ($\phi \rightarrow T_{\text{tick}}^-$, onset just before a tick boundary):

$$\tau_{\text{min}} = (M - 1) \cdot T_{\text{tick}} + \tau_{\text{RTT}}. \quad (2)$$

(b) WORST CASE ($\phi = 0$, onset exactly at a tick boundary):

$$\tau_{\text{max}} = M \cdot T_{\text{tick}} + \tau_{\text{RTT}}. \quad (3)$$

(c) EXPECTED CASE ($\phi \sim \text{Uniform}[0, T_{\text{tick}})$):

$$\tau_{\text{E}} = (M - 1/2) \cdot T_{\text{tick}} + \tau_{\text{RTT}}. \quad (4)$$

τ_{min} , τ_{E} , τ_{max} are all linear in M with identical slope T_{tick} . The spread $\tau_{\text{max}} - \tau_{\text{min}} = T_{\text{tick}}$ is exactly one tick.

PROOF. The alarm fires at $t_{\text{alarm}} = (k_0 + M) \cdot T_{\text{tick}}$, so $t_{\text{alarm}} - t_0 = (k_0 + M) \cdot T_{\text{tick}} - (k_0 \cdot T_{\text{tick}} + \phi) = M \cdot T_{\text{tick}} - \phi$. Adding τ_{RTT} gives (1). Substituting $\phi \rightarrow T_{\text{tick}}^-$ gives (2); $\phi = 0$ gives (3); integrating uniformly over $[0, T_{\text{tick}})$ gives (4). Linearity in M is immediate. QED.

The full proof and traceability appear in [L-DL-PROOF].

5. Reconciliation with the Profiles

Each profile statement makes one of τ_{min} , τ_{E} , τ_{max} operational. Under L_DL all are correct simultaneously.

Statement (literal)	L_DL quantity	Role
BE Thm 9: $\tau_{\text{detect}} \geq M \cdot T_{\text{tick}}$	τ_{max}	worst case
BFD 12.1: $100 \text{ ms} = (M-1) \cdot T_{\text{tick}}$	τ_{min} ($\tau_{\text{RTT}} = 0$)	best case
DDoS D1: $\tau_{\text{detect}} = (M-1) \cdot T_{\text{tick}}$	τ_{min} ($\tau_{\text{RTT}} = 0$)	best case (asympt. R)

COROLLARY 5.1 (BE Theorem 9 reformulated).

$\tau_{\text{detect}} \leq M \cdot T_{\text{tick}} + \tau_{\text{RTT}}$. Equality is attained only at $\phi = 0$; strict inequality holds on a ϕ -set of measure T_{tick} .

COROLLARY 5.2 (BFD / DDoS Theorem D1 reformulated).

$\tau_{\text{detect}} \geq (M - 1) \cdot T_{\text{tick}} + \tau_{\text{RTT}}$. Published p95 benchmark figures are upper percentiles and therefore approach τ_{max} , not τ_{min} .

COROLLARY 5.3 (Expected case).

$E[\tau_{\text{detect}}] = (M - 1/2) \cdot T_{\text{tick}} + \tau_{\text{RTT}}$. This is the

time-averaged latency under uniform onset phase, and is the single number that operator-facing documentation SHOULD cite.

The "= R_sat" wording in the DDoS profile is asymptotic in attack rate R, not in M; the volume-independence claim is unchanged, since neither tau_min nor tau_max depends on R.

6. Numerical Receipt

The lemma is checked against the synthetic benchmark of scripts/benchmark_coherence_bfd.py (N = 1000 vantages, tau_RTT = 5 ms) by scripts/validate_detection_latency_lemma.py. The machine-readable receipt is evidence/detection_latency_lemma_receipt.json (verdict PASS, maximum absolute error 0 ms). Every observed p95 equals tau_max (3) to the millisecond:

Variant	T_tick (ms)	M	tau_min (ms)	tau_max (ms)	p95 obs(ms)
V0 FMVPS-baseline	60000	1	5	60005	60005
V1 BFD-heartbeat-fast	50	3	105	155	155
V2 BFD-demand	1000	1	5	1005	1005
V3 BFD-echo	50	1	5	55	55
V4 BFD-hybrid	50	3	105	155	155

All five variants are explained by tau_max to the millisecond.

7. Recommended Reporting Convention

To prevent the one-tick disagreement from recurring, MVPS profiles and operator-facing material SHOULD adopt the following convention:

- o When reporting a benchmark upper percentile (e.g. p95), cite $\tau_{\max} = M \cdot T_{\text{tick}} + \tau_{\text{RTT}}$ (3).
- o When reporting a single representative latency, cite the expected value $\tau_E = (M - 1/2) \cdot T_{\text{tick}} + \tau_{\text{RTT}}$ (4).
- o When stating a best-case lower bound, cite $\tau_{\min} = (M - 1) \cdot T_{\text{tick}} + \tau_{\text{RTT}}$ (2), and label it as the best case explicitly.

Profiles citing a single formula without naming the case SHOULD be read as tau_max for safety (the worst-case bound).

8. Relationship to MVPS v4.0

L_DL imports only (i) the discrete-time tick-lattice model of standard sampled-data analysis [AstromWittenmark] and (ii) the additive-constant property of one-way signalling latency. It does NOT alter Theorems 1 through 9 of the MVPS v4.0 catalogue [MVPS-V4]; it refines the detection-latency inheritance of the BE, BFD, and DDoS profiles by making the previously implicit onset-phase assumption explicit. It is recorded as an auxiliary lemma in [MVPS-FOUNDATIONS].

9. Security Considerations

This document is a latency-accounting clarification and introduces

no new protocol mechanism. It does not change the threat model of any profile. One operational note: when a detection-latency figure is used to dimension a reaction deadline (for example, a DDoS mitigation trigger), operators SHOULD dimension against `tau_max` (3) rather than `tau_min` (2), since onset phase is not controllable by the defender and the adversary may, in the worst case, induce onset at a tick boundary ($\phi = 0$).

10. IANA Considerations

This document has no IANA actions.

Appendix A. Mathematical Core (Normative)

LEMMA `L_DL`. For $M \geq 1$, $T_{\text{tick}} > 0$, $\tau_{\text{RTT}} \geq 0$, and onset phase ϕ in $[0, T_{\text{tick}})$:

```
tau_detect(phi) = M*T_tick - phi + tau_RTT,
tau_min = (M - 1)*T_tick + tau_RTT      (phi -> T_tick^-),
tau_max = M*T_tick + tau_RTT            (phi = 0),
```

$\tau_E = (M - 1/2) * T_{\text{tick}} + \tau_{\text{RTT}}$ (phi uniform).

Proof: Section 4. Constructive witness:
scripts/validate_detection_latency_lemma.py reproduces the
per-variant table of Section 6 with maximum absolute error 0 ms
(receipt: evidence/detection_latency_lemma_receipt.json).

NON-CLAIM. L_{DL} does not assert a tighter bound than τ_{max} for an
adversary-chosen onset phase; $\phi = 0$ is achievable in principle,
so τ_{max} is the dimensioning quantity for security-sensitive
deadlines.
